(Received 3 April 2007; published 31 July 2007)

We study the performance of holonomic quantum gates, driven by lasers, under the effect of a dissipative environment modeled as a thermal bath of oscillators. We show how to enhance the performance of the gates by a suitable choice of the loop in the manifold of the controllable parameters of the laser. For a simplified, albeit realistic model, we find the surprising result that for a long time evolution the performance of the gate (properly estimated in terms of average fidelity) increases. On the basis of this result, we compare holonomic gates with the so-called stimulated Raman adiabatic passage (STIRAP) gates.

I. INTRODUCTION

The major challenge for quantum computation is posed by the fact that generically quantum states are very delicate objects quite difficult to control with the required accuracy—typically, by means of external driving fields, e.g., a laser. The interaction with the many degrees of freedom of the environment causes decoherence; moreover, errors in processing the information may lead to a wrong output state.

Among the approaches aiming at overcoming these difficulties are those for which the quantum gate depends very weakly on the details of the dynamics, in particular, the holonomic quantum computation (HQC) [1] and the so-called stimulated Raman adiabatic passage (STIRAP) [2–4]. In the latter, the gate operator is obtained acting on the phase difference of the driving lasers during the evolution, while in the former the same goal is achieved by exploiting the noncommutative analogue of the Berry phase collected by a quantum state during a cyclic evolution. Concrete proposals have been put forward, for both Abelian [5,6] and non-Abelian holonomies [7–12]. The main advantage of the HQC is the robustness against noise deriving from a imperfect control of the driving fields [13–20].

In a recent paper [21] we have shown that the disturbance of the environment on holonomic gates can be suppressed and the performance of the gate optimized for particular environments (purely superohmic thermal bath). In the present paper we consider a different sort of optimization, which is independent of the particular nature of the environment.

By exploiting the full geometrical structure of HQC, we show how the performance of a holonomic gate can be enhanced by a suitable choice of the loop in the manifold of the parameters of the external driving field: by choosing the optimal loop which minimizes the “error” (properly estimated in terms of average fidelity loss), our result is based on the observation that there are different loops in the parameter manifold producing the same gate and, since decoherence and dissipation crucially depend on the dynamics, it is possible to drive the system over trajectories which are less perturbed by the noise. For a simplified, albeit realistic model, we find the surprising result that the error decreases linearly as the gating time increases. Thus the disturbance of the environment can be drastically reduced. On the basis of this result, we compare holonomic gates with the STIRAP gates.

In Sec. II the model is introduced and the explicit expression of the error is derived. In Sec. III we find the optimal loop, calculate the error, make a comparison with other approaches, and briefly sketch how to treat a different coupling with the environment.

II. MODEL

The physical model is given by three degenerate (or quasidegenerate) states, |+,⟩, |−⟩, and |0⟩, optically connected to another state |G⟩. The system is driven by lasers with different frequencies and polarizations, acting selectively on the degenerate states. This model describes various quantum systems interacting with a laser radiation, ranging from semiconductor quantum dots, such as excitons [12] and spin-degenerate electron states [3], to trapped ions [8] or neutral atoms [7].

The (approximate) Hamiltonian modeling the effect of the laser on the system is (for simplicity, ℏ = 1) [8,12]

\[ H_0(t) = \sum_{j=+,-,0} \{ e_j |j⟩⟨j| + [e^{-i\epsilon t}\Omega_j(t)|j⟩⟨j|G⟩] + H.c.\} \]

where \( \Omega_j(t) \) are the time-dependent Rabi frequencies depending on controllable parameters, such as the phase and intensity of the lasers, and \( e \) is the energy of the degenerate electron states. The Rabi frequencies are modulated within the adiabatic time \( τ_{ad} \) (which coincides with the gating time), to produce a loop in the parameter space and thereby realize the periodic condition \( H_0(τ_{ad}) = H_0(0) \).

The Hamiltonian (1) has four time-dependent eigenstates: two eigenstates |\( E_i(t) \rangle, i = 1, 2 \rangle, called bright states, and two eigenstates |\( E_i(t) \rangle, i = 3, 4 \rangle, called dark states. The two dark states have degenerate eigenvalue \( e \) and the two bright states have time-dependent energies \( \lambda_\epsilon(t) = [\epsilon \sqrt{e^2 + 4|\Omega_\epsilon(t)|^2}]/2 \) with \( \Omega_2(t) = \sum_{i=e,0} |\Omega_i(t)|^2 \) [22].
The evolution of the state is generated by

$$U_t = T e^{-i H_0 dt} U_0,$$

where $T$ is the time-ordered operator. In the adiabatic approximation, the evolution of the state takes place in the degenerate subspace generated by $|+\rangle$, $|-\rangle$, and $|0\rangle$. This approximation allows to separate the dynamic contribution and the geometric contribution from the evolution operator. Expanding $U_t$ in the basis of instantaneous eigenstates of $H_0(t)$ (the bright and dark states), in the adiabatic approximation, we have

$$U_t = \sum_i e^{-i \int_0^t E_i(\tau) d\tau} |E_i(t)\rangle \langle E_i(t)|,$$

where

$$U_0 = T e^{i \int_0^t e V(t) dt},$$

here $V$ is the operator with matrix elements $V_{ij}(t) = \langle E_j(t)| \partial_t| E_i(t)\rangle$. The unitary operator $U_t$ plays the role of time-dependent holonomic operator and is the fundamental ingredient for realizing complex geometric transformation whereas $\sum_i e^{-i \int_0^t E_i(\tau) d\tau} |E_i(t)\rangle \langle E_i(t)|$ is the dynamic contribution.

Consider $U_t$ for a closed loop, i.e., $t=t_{\text{end}}$.

$$U = U_{\text{end}}^{-1} U_t.$$  

If the initial state $|\psi_0\rangle$ is a superposition of $|+\rangle$ and $|-\rangle$, then $U_t|\psi_0\rangle$ is still a superposition of the same vectors (in general, with different coefficients) [12]. Thus the space spanned by $|+\rangle$ and $|-\rangle$ can be regarded as the “logical space” on which the “logical operator” $U$ acts as a “quantum gate” operator. Note that for $t < t_{\text{end}}$ $U_t|\psi_0\rangle$ can be expanded in the two-dimensional space spanned by the dark states $|E_1(t)\rangle$ and $|E_2(t)\rangle$. It is important to observe that $U$ depends only on global geometric features of the path in the parameter manifold and not on the details of the dynamical evolution [1,12].

To construct a complete set of holonomic quantum gates, it is sufficient to restrict the Rabi frequencies $\Omega_i(t)$ in such a way that the norm $\Omega$ of the vector $\Omega = [\Omega_0(t), \Omega_1(t), \Omega_2(t)]$ is time independent and the vector lies on a real three-dimensional sphere [8,12]. We parametrize the evolution on this sphere as $\Omega_1(t) = \sin(\theta(t)) \cos(\phi(t))$, $\Omega_2(t) = \sin(\theta(t)) \sin(\phi(t))$, and $\Omega_0(t) = \cos(\theta(t))$ with fixed initial (and final) point in $\theta(0) = 0$, the north pole. By straightforward calculation we obtain the analytical expression for $V(t)$ in Eq. (4), $V(t) = \sigma_r \sin(\theta(t)) \phi(t)$, where $\sigma_r$ is the usual Pauli matrix written in the basis of dark states. Thus, the operator (4) becomes $U_t = \cos[\sigma_r(t) - i\sigma_r \sin(\alpha(t))]$, hence $\alpha(t) = \int_0^t d\tau \phi(\tau) \cos(\theta(\tau))$. Accordingly, the logical operator $U(5)$ is

$$U = \cos a - i \sigma_r \sin a,$$

where

$$a = a(t_{\text{end}}) = \int_0^{t_{\text{end}}} d\tau \phi(\tau) \cos(\theta(\tau)).$$
error is defined as the average fidelity loss, i.e.,
\[
\delta = \left< 1 - \hat{\mathcal{F}} \right> = 1 - \left< \langle \psi(0)|\hat{\rho}(t_0)|\psi(0) \rangle \right>,
\] (13)
where \( \langle \cdot \cdot \cdot \rangle \) denotes averaging with respect to the uniform distribution over the initial state \( |\psi(0)\rangle \).

The right-hand side of Eq. (13) can be computed by the following steps:

1. solving Eq. (11) in strictly second-order approximation; this approximation corresponds to replace \( \hat{\rho}(t - \tau) \) with \( \rho(0) \);
2. using the adiabatic approximation \( U(t - \tau, t) = \exp[i\tau \hat{H}_0(t)] \);
3. expanding the scalar product in Eq. (13) with respect to a complete orthonormal basis \( \{ |\varphi_n(t)\rangle \} \), \( n = 1, 2, 3 \), orthogonal to \( |\psi(t)\rangle \). In this way, one obtains
\[
\delta = \left< \sum_{n=1}^{3} \int_{0}^{t_{\text{end}}} dt G(t) |\langle \psi(t)|\hat{A}|\varphi_n(t) \rangle|^2 \right>,
\] (14)
where
\[
G(t) = \int_{0}^{t} d\tau \text{Re}[g(\tau)] \cos(\omega_{0n} \tau) + \text{Im}[g(\tau)] \sin(\omega_{0n} \tau)].
\] (15)

Here, \( \omega_{0n} = \omega_0 - \omega_n \) are the energy differences associated with the transition \( \psi_0 \leftrightarrow \varphi_n \), with \( \omega_0 = \epsilon, \omega_1 = \lambda_+, \omega_2 = \lambda_- \), and \( \omega_3 = \epsilon \).

The interaction between system and environment is expressed by the noise operator \( \hat{A} \) in Eq. (8). We shall now make the assumption that \( \hat{A} = \text{diag}(0, 0, 0, 1) \) in the \( |G\rangle, |\pm \rangle \), and \( |0\rangle \) basis. In this case the transition between degenerate states are forbidden, however the noise breaks their degeneracy, shifting one of them. In spite of its simple form, this \( \hat{A} \) is nevertheless a realistic noise operator for physical semiconductor systems [4].

### III. MINIMIZING THE ERROR

The problem can be stated in the following way: given the noise operator \( \hat{A} \) and the logical operator \( \hat{U} \), find a path on the parameter space (the surface of the sphere, described above) which minimizes the error \( \delta \).

The total error \( \delta \), given by Eq. (14), can be decomposed as
\[
\delta = \delta_{\text{r}} + \delta_{\text{pd}},
\] (16)
where the transition error, \( \delta_{\text{r}} \), is the contribution to the sum of the nondegenerate states (\( \omega_{0n} \neq 0 \)) and the pure dephasing error \( \delta_{\text{pd}} \) is the contribution of the degenerate states (\( \omega_{0n} = 0 \)). Thus
\[
\delta_{\text{pd}} = \frac{\pi}{8} \int_{0}^{t_{\text{end}}} dt \int_{0}^{\infty} \frac{d\omega}{\omega} \coth\left( \frac{\omega}{2T} \right) \times \sin(\omega t) \left( 1 + \frac{1}{2} \sin^2 2a(t) \right) \sin^4 \theta(t),
\] (17)
and
\[
\delta_{\text{r}} = \sum_{n=\pm}^{n=\pm} \frac{1}{8} \int_{0}^{t_{\text{end}}} dt \int_{0}^{\infty} \frac{d\omega}{\omega} \coth\left( \frac{\omega}{2T} \right) \times \sin(\omega t) \left( 1 + \frac{1}{2} \sin^2 2a(t) \right) \sin^4 \theta(t),
\] (18)
where
\[
\Gamma_{\text{on}} = J(\omega_{0n}) \left[ \coth \left( \frac{\omega_{0n}}{2T} \right) - \text{sgn}(\omega_{0n}) \right]
\] (19)
correspond to the transition rates calculated by standard Fermi golden rules, supposing, as usual, \( G(t) = G(0) \) for \( g(t) \) strongly peaked around \( t=0 \). In the following we define for simplicity
\[
K = \sum_{n=\pm}^{n=\pm} \frac{1}{8} \int_{0}^{t_{\text{end}}} dt \int_{0}^{\infty} \frac{d\omega}{\omega} \coth\left( \frac{\omega}{2T} \right) \times \sin(\omega t) \left( 1 + \frac{1}{2} \sin^2 2a(t) \right) \sin^4 \theta(t),
\] (20)

### A. Transition rate

As explained in Sec. II, the holonomic paths are closed curves on the surface of the sphere which start from the north pole. It turns out that the curve minimizing \( \delta_{\text{r}} \) can be found among the loops which are composed by a simple sequence of three paths (see the Appendix): evolution along a meridian (\( \phi = \text{const} \)), evolution along a parallel (\( \theta = \text{const} \)), and a final evolution along a meridian to come back to the north pole.

The error \( \delta_{\text{r}} \) in (18), depends on \( a \) given by Eq. (7). \( \theta_M \) (the maximum angle spanned during the evolution along the meridian), \( \Delta \phi \) (the angle spanned along the parallel), and angular velocity \( v \). We allow \( \Delta \phi = 2\pi \) which corresponds to cover more than one loop along the parallel. The velocity along the parallel is \( v(t) = \dot{\phi}(t) \sin \theta \) and that along the meridian is \( v(t) = \dot{\theta}(t) \). In the following we assume that \( v \) is constant, and it cannot exceed the maximal value of \( v_{\text{max}} \), fixed by adiabatic condition \( v_{\text{max}} \approx \Omega \).

The parameters \( a, \theta_M \) and \( \Delta \phi \) are connected by the relation \( a = \Delta \phi (1 - \cos \theta_M) \). The error \( \delta_{\text{r}} \) is then
\[
\delta_{\text{r}} = \delta_{\text{r}}^M + \delta_{\text{r}}^P,
\] (21)
where
\[
\delta_{\text{r}}^M = K \left( \theta_M - \frac{1}{4} \sin 4 \theta_M \right)
\] (22)
is the contribution along the meridian and
\[
\delta_{\text{r}}^P = K \left( a \sin \theta_M \sin^2 2 \theta_M \right)
\] (23)
is the contribution along the parallel.

In Fig. 1 \( \delta_{\text{r}} \) is plotted for \( a = \pi/2 \) and \( a = \pi/4 \) (corresponding to NOT and Hadamard gate, respectively) as a function of \( \theta_M \). One can see that \( \delta_{\text{r}} \) has a local minimum for \( \theta_M = \pi/2 \) and a global minimum for \( \theta_M = 0 \) where the error vanishes. This suggests that the best choice is to take \( \theta_M \) as small as possible.
It is interesting to consider the dependence of $\delta_\nu$ also on the evolution time $t_{ad}$. For simplicity, we set the velocity $v=v_{\text{max}}$. In this case, changing $\theta_M$ (and then $\Delta\phi$) corresponds to a change in the evolution time. We obtain

$$\theta_M = \arccos \left( 1 - \frac{a}{2\pi m} \right),$$

where

$$m = \frac{1}{4\pi a} \left( (v_{\text{max}}t_{ad})^2 + a^2 \right).$$

Using these relations, $\delta_\nu^M$ and $\delta_\nu^p$, given by (21) and (22) become functions of $t_{ad}$, $v_{\text{max}}$, and $a$. Note that $m$ measures the space covered along the parallel, in fact $\Delta\phi=2\pi m$.

In Fig. 2 we see the behavior of $\delta_\nu$ as a function of $v_{\text{max}}t_{ad}$. The first minimum for both curves corresponds to $\theta_M=\pi/2$, then the curves for long $t_{ad}$ decrease asymptotically to zero corresponding to the region in which $\theta_M \to 0$. In this regime we have $\delta_\nu \approx 1/t_{ad}$ which is drastically different from the results obtained with other methods where $\delta_\nu \approx t_{ad}$ (see Refs. [4,25] and below Sec. III C). It should be observed that this surprising result is a merit of holonomic approach which allows to choose the loop in the parameter space, without changing the logical operation as long as it subdents the same solid angle. Observe that small $\theta_M$ and long $t_{ad}$ mean large value of $m$, i.e., multiple loops around the north pole.

Figure 2 shows that, for a given gate, there is a critical value $k_c$ of $v_{\text{max}}t_{ad}$ which discriminate between the choice of $\theta_M$ (e.g., $k_c=6$ for the Hadamard gate and $k_c=25$ for the NOT gate). For $v_{\text{max}}t_{ad} < k_c$ the best choice for the loop is $\theta_M=\pi/2$; for $v_{\text{max}}t_{ad} > k_c$ the best choice is the value of $\theta_M$ determined by Eqs. (23) and (24).

Note that the region $v_{\text{max}}t_{ad} > k_c$ is accessible with physical realistic parameters [12]. For example, if we choose the laser intensity $\Omega=20$ meV and $v_{\text{max}}=\Omega/50$ (for which values of the nonadiabatic transitions are forbidden), the critical parameter corresponds to the critical time of 15 ps for the Hadamard gate and 42 ps for the NOT gate.

B. Pure dephasing

Until now we have ignored the pure dephasing effect because we have assumed that it is negligible in comparison with the transition error for long evolution time. Now, we check that the pure dephasing error contribution can indeed be neglected. We can write the pure dephasing error using Eq. (17) and splitting to parallel and meridian part as

$$\delta_{pd}^p = \int_0^{t_{ad}} dt \int_0^\infty d\omega \frac{J(\omega)}{\omega} \coth \left( \frac{\omega}{2T} \right) Q[a(t)] \sin \omega t \sin^4 \theta_M,$$

and

$$\delta_{pd}^M = \int_0^{\theta_M v_{\text{max}}} dt \int_0^\infty d\omega \frac{J(\omega)}{\omega} \coth \left( \frac{\omega}{2T} \right) Q[a(t)]$$

$$\times \sin \omega t \left( \sin^2(v_{\text{max}}t) + \sin^2 \left( \theta_M \left( 1 - \frac{v_{\text{max}}t}{\theta_M} \right) \right) \right),$$

where $Q[a(t)]=1+1/2 \sin^2[2a(t)]$.

To estimate $\delta_{pd}$ we assume that $t_{ad}$ is longer with respect to the characteristic time of the bath. Remembering that $J(\omega) \approx \omega$, the pure dephasing error behavior along the parallel part at the temperature $T$ is

$$\delta_{pd}^p \propto \begin{cases} 
\left( \frac{1}{t_{ad}} \right)^{s+3}, & T \ll 1/t_{ad}, \\
\left( \frac{T}{t_{ad}} \right)^{s+2}, & T \gg 1/t_{ad},
\end{cases}$$

while along the meridian is

$$\delta_{pd}^M \propto \left( \frac{1}{t_{ad}} \right)^3.$$
C. Comparison between HQC and STIRAP

We make a comparison between holonomic quantum computation (HQC) and the STIRAP procedure which is an analogous approach to process quantum information. The STIRAP procedure [2,4] is, in its basic points, very similar to the holonomic information manipulation. The level spectrum, the information encoding, the evolution produced by adiabatic evolving laser are exactly the same. The fundamental difference is that in STIRAP the dynamical evolution is fixed (we must pass through a precise sequence of states) and then the corresponding loop in the parameter space is fixed. In particular, we go from the north pole to the south pole and back to the north pole along meridians. Since the loop, as in our model, is a sequence of meridian-parallel-meridian path, we can calculate the error and make a direct comparison. In this case, the transition error results proportional to \( \delta_{tr} \propto t_{ad} \) and grows linearly in time while for HQC \( \delta_{tr} \propto 1/t_{ad} \). Therefore, the HQC is fundamentally the favorite for long applications. Moreover, we can show that the freedom in the choice of the loop allows us to construct HQC which perform better than the best STIRAP gates. In Ref. [4] the minimum error (not depending on the evolution time) for STIRAP was obtained reaching a compromise between the necessity to minimize the transition, pure dephasing error, and the constraint of adiabatic evolution. With realistic physical parameters [21] \( \{J(\omega)\sim k\omega^3 e^{-(\omega/\omega_o)^2}, \Omega=10 \text{ meV}, \epsilon=1 \text{ eV}, v_{max}=\Omega/50, k=10^{-2} (\text{meV})^2, \omega_o=0.5 \text{ meV and for low temperature}, \) the total minimum error in Ref. [4] is \( \delta_{\text{STIRAP}}=10^{-3} \). With the same parameters, we still have the possibility to increase the evolution time in order to reduce the environmental error. However, for evolution time \( t_{ad}=50 \text{ ps} \) we obtain a total error \( \delta=1.5 \times 10^{-4} \) for the NOT gate and \( \delta=4 \times 10^{-5} \) for the Hadamard gate, respectively. As can be seen, the logical gate performance is greatly increased.

D. More general noise

Until now we have discussed the possibility to minimize the environmental error by choosing a particular loop in the parameter sphere but the structure of the error functional clearly depends on the system-environment interaction. Then one might wonder if the same approach can be used for a different noise environment.

For this reason, we now briefly analyze the case of noise matrix in the form \( A=\text{diag}(0,1,0,-1) \). Again, for long evolution we can neglect the contribution of the pure dephasing and focus on the transition error. In this case the interesting part of the error functional takes the form

\[
\delta_{tr} = K \left[ \left( \frac{1}{2} \sin 2\theta \cos 2\theta \right)^2 + \left( \sin \theta \sin 2\phi \right)^2 \right].
\]

Even if the analysis in this case is much more complicated, it can be seen that \( \delta_{tr} \) has an absolute minimum for \( \theta_M=0 \). The long time behavior is the same \( \delta_{tr} \propto 1/t_{ad} \) such that the results are qualitatively analogous to the above ones: for small \( \theta_M \) loops (or long evolution at fixed velocity) the holonomic quantum gate presents a decreasing error. Then even in this case it is possible to minimize the environmental error.
a $\Delta \phi_2$ angle), and finally a segment to the north pole along a meridian. Let us consider two closed curves $C_1^1$ and $C_1^2$ in $C_1$ subtending the same solid angle $a$ with, respectively, $\theta_1$ and $\theta_2$ as maximum angle spanned during the evolution along the meridian. First we analyze (20) along the meridian. Without losing generality, we can take $\theta_1 < \theta_2$; it is clear from Eq. (21) that the value of $\delta_0$ along the meridian for $C_1^1$ is smaller that for $C_1^2$: $\delta_{C_1}^M < \delta_{C_1}^M$. We note from Eq. (21), suitable extended to $C_2$, that the two paths along the meridians depends only on $\theta_2$ and then produce the same error of $C_1^2$,

$$\delta_{C_1}^M < \delta_{C_1}^M = \delta_{C_2}^M. \quad (A1)$$

The difference between the contribution along the parallel is

$$\delta_{C_2}^P - \delta_{C_1}^P = \Delta \phi_2 \left( \sin \theta_1 \sin^2 2 \theta_2 - \frac{1 - \cos \theta_1}{1 - \cos \theta_2} \sin \theta_2 \sin^2 2 \theta_2 \right) \quad (A2)$$

and

$$\delta_{C_2}^P - \delta_{C_1}^P = \Delta \phi_2 \left( \sin \theta_1 \sin^2 2 \theta_2 - \frac{1 - \cos \theta_1}{1 - \cos \theta_2} \sin \theta_2 \sin^2 2 \theta_2 \right). \quad (A3)$$

Analysis of the positivity of the quantities given by Eqs. (A2) and (A3) shows that $\delta_{C_2}^P$ cannot be at the same time smaller than $\delta_{C_1}^P$ and $\delta_{C_2}^P$ in fact, there are two possibilities: If $\delta_{C_2}^P > \delta_{C_1}^P$, from Eqs. (A1) and (A3),

$$\delta_{C_2}^P = \delta_{C_2}^M + \delta_{C_2}^P > \delta_{C_1}^M + \delta_{C_1}^P = \delta_{C_1}^P, \quad (A4)$$

and the best closed curve is $C_1^1$. If $\delta_{C_2}^P > \delta_{C_1}^P$, from Eqs. (A1) and (A2),

$$\delta_{C_2}^P = \delta_{C_2}^M + \delta_{C_2}^P > \delta_{C_1}^M + \delta_{C_1}^P = \delta_{C_1}^P, \quad (A5)$$

and the best closed curve is $C_1^2$.

In the same way it can be shown that any closed curve in $C_1$ can be replaced by a closed curve in $C_2$ with smaller error.

[22] The explicit expression for the bright states is $|E_i\rangle = \frac{1}{\sqrt{\xi}} (\Omega |e\rangle + \xi |\psi_i\rangle)$ and $|E_f\rangle = \frac{1}{\sqrt{\xi}} (-\Omega |e\rangle + \xi |\psi_i\rangle)$, for the dark states is $|E_i\rangle = 1/\sqrt{\Omega |\psi_i\rangle + \Omega_i |+\rangle + \Omega_i |\pm\rangle - (\Omega^2 - |\Omega_i|^2) |0\rangle}$ and $|E_f\rangle = 1/\sqrt{\Omega |\psi_i\rangle + \Omega_i |+\rangle + \Omega_i |\pm\rangle - |\Omega_i|^2}$.
